Abstract—This letter presents the first ultra-lightweight transmitter based on electromagnetic emanation to send embedded intellectual properties (IP) identity (ID) quickly and discreetly. The proposed solution is based on a binary frequency shift keying (BFSK) transmitter that ensures an exceptionally high data rate. In addition, we present a coherent demodulation method using slippery window spectral analysis to recover data outside the device. The hardware resources occupied by the transmitter represent less than 0.022% of a 130 nm Microsemi Fusion FPGA. The experimental bitrate of the data transmission is around 500 times higher than the bitrate available for other state of the art spy circuitry using power consumption. In comparison with other works, our proposal goes clearly towards using a spy circuit in an industrial context for IP protection.

Index Terms—IP protection, side channel, electromagnetic emanation analysis.

I. INTRODUCTION

For digital circuit design the re-use of embedded intellectual properties (IP) is more and more important due to prohibitive cost of ASIC design. Nevertheless the IP business suffers from a lack a security due to the intrinsic form of IPs sales and exchanges. Many dedicated threats target the IP life cycle and result to revenues losses for the IP designers [1]. The IP threat model includes illegal re-use, illegal sales, cloning (illegal copy) of the IP. The extent of threats targeting IPs is linked to the type of IP: software IPs (typically hardware description language files), firmware IPs (synthesized netlist), and hardware IPs (FPGA bitstream or physical layout).

One of the solutions for the IP designers to protect their intellectual property is to be able to detect the presence of a copy of an IP embedded in a digital device by using IP identification. Works on IP watermarking and IP fingerprinting try to provide the IP identification service. But, most of the time the published solutions are not practical mainly because of the complexity of the watermarking/fingerprinting verification scheme [2]. Efficient IP identification scheme needs to be contactless, rapid and ultra-lightweight. Up to now, these three characteristics are not available in the state-of-the-art. To meet these requirements, in this letter we propose an ultra-lightweight binary frequency shift keying (BFSK) transmitter to forward IP identity (that could be generated for example by a feedback shift-register or a physical unclonable function [1]) discreetly using an electromagnetic channel. Such circuit is usually called “spy circuitry”. Using the electromagnetic channel, it is possible to contactless check the presence of an IP inside a digital device.

The rest of this letter is organized as follows. In Section 2, we present related works. In Section 3, we detail the proposed electromagnetic communication of data (i.e. IC/IP information). In Section 4, we present a method to analyze the electromagnetic spectrum to BFSK signal demodulation and in Section 5 we present our conclusions.

II. RELATED WORK

Well-known threat in cryptographic engineering is side channel attacks [3]. Most of the dynamic characteristics of both hardware and software implementations of cryptographic primitives can be used for side channel analysis: computation time, power consumption, electromagnetic radiation, optical radiation, even the sound produced during computation. These side channels can be used as transmission channels to send intellectual property data from a device or an embedded IP. For example in [4], the thermal channel representing a contactless communication was used to transfer information from an embedded tag to a remote receiver. However the embedded thermal tag used in this commercial solution requires a relatively large area (255 Spartan-3 slices). In [5], the authors propose using two shift registers to generate a recognizable signature-dependent power consumption pattern to reveal the IP signature. Power consumption was also used in [6] to communicate the IP identity. To reinforce such work, the authors of [7] propose using the power supply signal of an IP as a physical hash function for fingerprinting.

Related works can be found also in the malicious hardware field such as hardware Trojans design. Such systems use side channels to forward secret information such as a symmetric cipher key from cryptographic hardware implementation [8], [9], but also to cause or to amplify side-channel leakage of cryptographic hardware [10].

Except [4], all the related works use power consumption as a communication channel which is not contactless. Unlike the proposed solution, all the related works are not lightweight.
and rapid as this letter will show.

III. PROPOSED EM COMMUNICATION OF DEEP DATA

Electromagnetic radiation is an efficient side channel since, unlike measurement of power consumption, electromagnetic radiation can be measured locally. One of the main advantages of this side channel is that it is impossible to hide the leak concerning electromagnetic radiation by using a global countermeasure. Moreover the electromagnetic test bench is not expensive (less than US$ 10K without an oscilloscope, which is the most expensive component). Last but not least, a spectral analysis of the electromagnetic radiation provides information on the oscillating structure such as a ring-oscillator [11]. For all these reasons, we use the electromagnetic channel for our IP identification scheme. To this end, we designed an ultra-lightweight BFSK transmitter which could be activated outside the device by an ID checker or internally by a specific event (e.g. specific input sequence, internal data value, system state). Note that an enable signal is required to reduce the power consumed by the ring oscillator. Moreover, a permanently activated transmitter could be detected more easily by a spectral analysis of electromagnetic emanations of the device and could also cause local heating and premature aging of the chip.

BFSK is one of the common modulation schemes used in digital communication. The binary data are sent using a sinusoidal carrier at two frequency tones \( f_0 \) and \( f_1 \), representing high ('1') and low ('0') logic levels. The binary data arriving at the transmitter input at certain bitrates determine the commutation of the tones at the transmitter output. The proposed BFSK transmitter uses a dedicated configurable ring-oscillator, as shown in Figure 1. The configurable ring-oscillator is designed using one multiplexor, \( N+K \) delay elements, and a feedback chain controlled by a NAND gate for activation of transmission to reduce power consumption. Actually, the transmitter is used only during a short time when the enable signal is high, and it consumes power only during this small piece of time. The power consumption of this transmitter is thus completely negligible.

Input data controls the multiplexor, as shown in Figure 1. When input data is low, the configurable ring oscillator uses \( N \) delays and its oscillation frequency is \( f_0 \). When input data is high, the configurable ring oscillator uses \( N+K \) delays and its oscillation frequency is \( f_1 \). Since the ring oscillator’s oscillation frequency decreases with an increase in the number of delay elements, frequency \( f_0 \) is higher than frequency \( f_1 \). These two frequencies have to be selected precisely to select precisely the two frequencies \( f_0 \) and \( f_1 \) using parameters \( N \) and \( K \). Fig. 2 shows the configurable ring oscillator frequencies evolution with \( N \) ranging from 0 to 4, and \( K \) ranging from 1 to 5. According to Fig. 2, \( f_0 \) can be chosen between 119 MHz (\( N=4 \)) and 385 MHz (\( N=0 \)) and \( f_1 \) can be chosen between 70 MHz (\( N=4, K=5 \)) and 280 MHz (\( N=0, K=1 \)).

The number of FUSION tiles used by the BFSK transmitter is very low, i.e. from 3 tiles (\( N=0, K=1 \)) to 11 tiles (\( N=4, K=5 \)). These values are equivalent to less than 0.022% and less than 0.080% of the total number of tiles included in the targeted 600K-gate FUSION FPGA, respectively. This very small number of tiles is very promising for good dissimulation of the BFSK transmitter inside the sea of gates/tiles. For XILINX and ALTERA SRAM FPGAs the BFSK consumes from 2 4-input- LUT (\( N=0, K=1 \)) to 10 4-input- LUT (\( N=4, K=5 \)). To evaluate its size in ASIC implementations, the gate count is estimated using the Virtual Silicon standard cell library based on the UMC L180 0.18 µm 1P6M Logic process (UMCL18G212T3 [12]). The delay gate count is estimated by the gate count of a standard NOT gate, 0.67 EG, and that of the standard multiplexor, 2.33 EG. The standard NAND gate uses 1 EG. So the number of gates of the whole BFSK transmitter ranges from 4.67 EG (\( N = 0, K = 1 \)) to 10.03 EG (\( N = 4, K = 5 \)). Note that one flip-flop requires between 5.33 EG and 12.33 EG to store a single bit [12].

The small requirement of logical resources of the proposed spy circuitry makes reverse engineering it harder, although not impossible [13]. Even with recent CMOS technologies, the attacker can reverse engineer ICs using a scanning electron

microscope and an automatic tool for circuitry extraction [13], [14]. Nevertheless, the smaller the piece of hardware used for BFSK transmitter the harder it is to detect during reverse engineering. Detection of the transmitter using standard Trojan detection methods [15], [16] is not feasible because the transmitter does not change the data path of the circuit and because of the ultra-low signal-to-noise ratio on the electromagnetic channel, as shown in our experimental results below (Section 4).

IV. EXPERIMENTAL RESULTS

The electromagnetic radiation of the device was evaluated using the near-field electromagnetic analysis test bench described in [11] with a spectral range limited to 100 MHz and 1 GHz. Standard devices aimed at direct BFSK demodulation cannot be used for these relatively high frequencies. Available integrated BFSK demodulators are limited to a few dozen megahertz. For this reason, we developed a dedicated BFSK demodulation scheme for our needs, in which a spectral analysis of the low noise amplifier output (a component of the test bench) is performed to measure the \( f_0 \) and \( f_1 \) spectral contribution. The transmitted high (low) level is detected when \( f_1 \) spectral contribution is higher (lower) than that of \( f_0 \).

Fig. 3 illustrates the spectral analysis of the BFSK transmitter’s electromagnetic emission when \( N = 1 \) and \( K = 1 \), which corresponds to a small transmitter with high frequencies \( (f_1=189.2 \text{ MHz and } f_0=272.2 \text{ MHz}) \).

For the spectral analysis, a 16 384 points FFT was computed. This figure presents a zoom (X and Y axis) on the global spectrum of the local electromagnetic emission of the circuit when the BFSK transmitter sends a ‘1’ (in red) and when the BFSK transmitter sends a ‘0’ (in blue).

![Fig. 3 Parts (zoom in x-axis and y-axis) of the electromagnetic emission spectral analysis of the proposed BFSK transmitter when it sends a high level at \( f_1=189.2\text{MHz} \) (in red) and when it sends a low level at \( f_0=272.2 \text{ MHz} \) (in blue).](image)

Notice also that we placed a small antenna in the close vicinity of the ring. The amplitude of the spectral rays at 180, 200, 220, 240, 260, 280 MHz are very high compared to the two spectral rays at 189.2 MHz and 272.2 MHz. However, we have cut the upper part of the spectrum in order to see the two interesting rays (at 189.2 MHz and 272.2 MHz). These frequencies correspond to the spectral contribution of the BFSK frequencies \( f_0 \) and \( f_1 \).

Without knowledge of the BFSK parameters, the electromagnetic transmission cannot be easily detected because it cannot be distinguished from spectral noise. The signal-to-noise ratio of the BFSK transmission in Fig. 3 is -135 dB for a 1 GHz bandwidth. Such an ultra-low SNR represents efficient protection against unwanted BFSK transmitter detection via a side channel. However, knowing the \( N \) and \( K \) parameters, the BFSK designer can calibrate the demodulation (determine the two frequencies) by electromagnetic analysis of the ring oscillators based on the differential spectral analysis according to [11].

The spectral contribution of the two BFSK frequencies during transmission (which is limited by the transmitter enable signal) at the low-noise amplifier output is measured to determine the transmitted bit sequence. In order to apply the demodulation technique described here, called coherent demodulation, theoretically the bitstream rate (bitrate) is limited to 0.5 times the frequency difference between \( f_1 \) and \( f_0 \).

In the case shown in Fig. 3, theoretically the maximum bitrate is 41.5 Mbps (theoretically limited to 53 Mbps when \( N = 0 \) and \( K = 1 \)). The bitrate of best IP identification methods using power consortium in the literature is always less than 1 Kbps even with recent device (i.e. XILINX Virtex V) [6-9].

For the coherent demodulation of the electromagnetic radiation, we propose a slippery window spectral analysis. Indeed, overall spectral analysis masks the effects of the nonstationarity of the signal and therefore provides no information about its temporal evolution. Slippery window spectral analysis is a three-dimensional representation of the signal: amplitude, frequency, and time. It requires two quantities \( F_w \), the width of the FFT window frame and the difference \( \Delta \tau \) between two frames. For our experiment, we chose \( F_w \) equal to 16 384 points (2\(^{14}\)-point FFT) and \( \Delta \tau \) equal to 100 points. For each frame, the FFT provides the software demodulator with the amplitude of signals \( f_0 \) and \( f_1 \) which enables the demodulator to distinguish between a transmitted 1 or 0.

To illustrate data transmission from the circuit via the electromagnetic channel, we used a shift register that stored the following 16-bit sequence: “1011110111011100”. The clock frequency of the shift register is 500 kHz. When the enable signal of the transmitter is given, the sequence is sent cyclically to the BFSK transmitter, which transmits it via the electromagnetic channel. Fig. 4 gives the result of the coherent demodulation obtained at a 500 Kbps bit rate (500 times more than [6-9]), which served as a proof of concept.

V. CONCLUSION

In this letter, we have presented an ultra-lightweight transmitter of IP identity using the electromagnetic side channel for FPGA implantation. Based on a configurable ring oscillator, our solution exploits a BFSK signal to transmit information by way of the electromagnetic channel. By performing a slippery window spectral analysis of the near
field electromagnetic emanations captured locally over the BFSK transmitter circuitry, the proposed transmission achieves a high bitrate (theoretically limited to 53 Mbps with a Microsemi Fusion FPGA), which has not been achieved before. Moreover, the transmitter occupies very small area.

For the highest frequency and data rate, our solution requires 4.67 equivalent gates, which is less than the requirement of a small D-flip-flop. Such a small area makes reverse engineering of the chip very difficult and detection of the transmitter using standard Trojan detection methods is not realistic.
